Keywords: First-principles calculations Magnesium alloys Stacking-fault energy Alloying effect

#### ABSTRACT

Generalized stacking-fault energies (GSFEs) of basal-plane stacking faults I<sub>1</sub> and I<sub>2</sub> in Mg alloys have been studied based on first-principles calculations, where 43 alloying elements were considered. It is found that the most contributing features of alloying elements to GSFEs are bulk modulus, equilibrium volume, binding energy, atomic radius and ionization energy. Both bulk modulus and ionization energy exhibit positive relationships with GSFEs, and the others show opposite relationships. Multiple regressions have been performed to offer a quantitative prediction for basal-plane GSFEs in Mg-X systems. GSFEs, alloying effects of elements and the prediction model established within this work may provide guidelines for new Mg alloys design with better ductility.

#### 1. Introduction

Magnesium (Mg) and its alloys are considered as promising structural materials for various applications in aerospace, automobile and microelectronics industries [1], where a reduction in weight is necessary for high energy efficiency. Mg alloys with a low mass density, which is 23% of steel and 66% of aluminum, is considered as the most lightweight structural materials. However, the potential use of Mg alloys is limited due to their low ductility and poor formability, which are due to the fact that there are only two independent slip systems on the basal plane in metals with hexagonal close packed (HCP) structures, such as Mg, far from sufficient compared to that in face centered cubic (FCC) structures. Controlling the microstructural morphology and microdefects, reducing the activation energy of basal plane slip and introducing more non-basal slip modes are important to improve the ductility of magnesium alloys.

Stacking-fault energy (SFE) is a fundamental parameter in metal and alloys, which is related to plastic deformation. Generalized stacking-fault energies (GSFEs) could be calculated along the minimum energy pathway (MEP) in a fault plane. Particularly, local

\* Corresponding authors. E-mail addresses: hong.zhu@sjtu.edu.cn (H. Zhu), xqzeng@sjtu.edu.cn (X. Zeng). minimum and maximum of GSFEs are noted as stable (or intrinsic) SFE and unstable SFE respectively. On the other hand, deformation mechanisms in HCP metals contain basal-plane and non-basal plane slip systems. The slip modes of dislocations in HCP metals are rationalized based on the GSFEs of these slip systems [2]. In other words, the slip systems with a lower GSFE would be favorable during plastic deformation. The motion of basal-plane dislocations is usually dominant in Mg alloys since the basal-plane GSFEs including SFEs of I<sub>1</sub> and I<sub>2</sub> faults are much lower than that of prismatic and pyramidal slip systems [3,4]. The nucleation of <c + a> dislocations, were found to be activated by the basal-plane intrinsic I<sub>1</sub> stacking faults [5]. Basal-plane I<sub>1</sub> stacking fault energy was also proved to influence the behavior of <c + a> dislocations in non-basal slip systems of Mg alloys [2].

Addition of alloying elements into Mg matrices has been reported as an effective method to modify SFEs and improve ductility of Mg alloys [6]. Sandlobes et al. [5] investigated the relationship between ductility and SFEs in pure Mg and Mg-Y alloys. Their work revealed that ductility of Mg-Y alloys was enhanced by the high activity of the <c + a> dislocations as a result of the reduced SFEs of I<sub>1</sub> faults. Han et al. [7] revealed that basal-plane GSFEs in Mg alloys were strongly relatated to the evolution of dislocations and tunable upon doping. Their work showed that Li addition to Mg increased GSFEs and favored dislocation-mediated processes which

tend to generate trailing partials on basal planes, whilst Al addition decreased GSFEs and favored sequential faulting across the basal plane. Zhang et al. [8] calculated the intrinsic SFEs of basal I<sub>2</sub> faults with 52 solute elements in Mg-X alloy systems and found that intrinsic SFEs of I<sub>2</sub> increased with a decrease in atomic radius or increase in ionization energy of alloying elements.

Previous research mentioned above all reached a conclusion that basal-plane stacking faults play a dominating role in deformation mechanisms of Mg alloys [2-5,7,8], and a large number of alloying elements have been considered for the determinations of the intrinsic SFEs of I<sub>2</sub> faults [8], while few people focused on unstable SFEs of I<sub>2</sub> faults as well as the intrinsic and unstable SFEs of I<sub>1</sub> faults in alloying systems, which are of great importance for evaluating GSFEs in basal-plane slip systems and understanding the deformation mechansims in Mg alloys. In this work, we calculated intrinsic and unstable SFEs of both I1 and I2 faults for Mg alloys. Forty-three regular alloying elements for Mg were considered to give an informative and exhaustive GSFE database for Mg binary alloy systems, i.e., Ag, Al, Au, Ba, Be, Bi, Ca, Cd, Co, Cr, Cu, Fe, Ga, Hf, Hg, In, Ir, K, La, Li, Mn, Mo, Na, Nb, Ni, Pb, Pd, Pt, Re, Rh, Ru, Sc, Sm, Sn, Sr, Ta, Tc, Ti, Tl, V, W, Y, Zn and Zr. To understand the alloying effects on GSFEs of Mg alloys, we selected several possible properties of alloying elements and doped systems which might influence the GSFEs in Mg-X alloys. Statistical analyses were performed to identify the most contributing features to GSFEs. Together with basal-plane GSFEs in Mg and Mg-X alloys, the contributing properties of alloying elements to GSFEs found in this work are expected to be a useful guideline for the design of new Mg alloys with good ductility and formability.

#### 2. Computational methods

In this work, we have chosen the growth fault I<sub>1</sub> and the deformation fault I<sub>2</sub> for basal-plane GSFE calculations in pure Mg and Mg-X binary alloys. According to the periodical atomic configuration in HCP structures, a perfect sequence of atomic layers could be described as ... ABABAB ..., and the growth fault I<sub>1</sub> could be formed by removing a basal plane in a perfect structure and then shearing the atomic layers above the fault with  $\hat{\boldsymbol{b}} = \frac{1}{3} [10\overline{10}]$ :

$$\dots$$
 ABABABAB...  $\rightarrow$   $\dots$  ABABBABA...  $\rightarrow$   $\dots$  ABABCBCB... (1)

while the deformation fault I<sub>2</sub> could be formed by shearing half of the atomic layers in a perfect structure with  $\mathbf{\tilde{b}} = \frac{1}{3} \begin{bmatrix} 10\bar{1}0 \end{bmatrix}$ :

$$\dots$$
ABABABAB...  $\rightarrow \dots$ ABABCACA... (2)

With the stacking faults introduced to the perfect structure, the generalized stacking-fault energies could be calculated using the following equation:

$$\gamma_{\rm GSF} = \frac{E_{\rm GSF} - E_0}{A} \tag{3}$$

where  $\gamma_{\text{CSF}}$  represents the GSFE of a stacking fault structure,  $E_{\text{CSF}}$  represents the energy of the stacking faulted structure,  $E_0$  represents the energy of a perfect structure, and *A* represents the surface area of the faulting plane.

Density functional theory (DFT) calculations were performed within the Vienna Ab-initio Simulation Package (VASP) [9–11]. The generalized-gradient-approximation (GGA), Perdew-Burke-Ernzerhof (PBE) exchange-correlation functional and projector augmented wave method (PAW) were used [12–14].

The (0001) Mg slab with 12 atomic layers and  $2 \times 2$  primitive cell along surface plane was adopted in our simulations for pure Mg and Mg-X binary alloys, as illustrated in Fig. 1. To avoid the interactions between adjacent images, 15 Å vacuum was employed along the [0001] direction. In the cases of Mg-X systems, one Mg atom in the 6th layer near the stacking-fault plane was substituted with an X atom, corresponding to the doping concentration of 25.0

**Fig. 1.** Atomic configuration of (a) perfect, (b)  $I_2$  faulted, (c)  $I_1$  faulted and (d)  $I_1'$  faulted (0001) Mg<sub>47</sub>X slab. Each faulted slab contains a stacking-fault interface in the middle, where the local atomic configuration is FCC-like.

at.% on the doping plane and 1.1 at.% in the entire Mg-X systems. To calculate the GSFEs of the I<sub>2</sub> faults, a generalized stacking fault pathway was built from a perfect slab to an I<sub>2</sub> faulted slab, in which the I<sub>2</sub> faulted slab was formed by shearing half of the atomic layers in a perfect slab with the Burger vector  $\mathbf{\bar{b}} = \frac{1}{3} \begin{bmatrix} 10\bar{1}0 \end{bmatrix}$ , as shown in Fig. 1(a,b). To calculate the GSFEs of the  $I_1$  faults, a generalized stacking fault pathway was built from an  $I_1$  faulted slab to an  $I_1'$ faulted slab, during which the position of faulting plane has climbed from one atomic layer to an adjacent layer. In this procedure, the two faulted slabs  $I_1$  and  $I_1'$ , shown in Fig. 1(c,d), represented similar faulted structures both with I1 faults but located on different atomic layers. The bottom half atomic layers in an I<sub>1</sub> faulted slab were shifted a Burgers vector  $\mathbf{b} = \frac{1}{3} \begin{bmatrix} 10\overline{1}0 \end{bmatrix}$  to form an  $I_1'$  faulted slab, and the two endpoints of the fault pathway, I1 and I1' structures, were expected to exhibit similar stacking-fault energies. The climbing-image nudged elastic band (CINEB) methods [15] were used to compute GSFE curves along the MEP and to acquire GSFE at saddle point as the unstable SFE. In our simulations, k-point meshes of  $8 \times 8 \times 1$   $\Gamma$ -centered grids and a convergence criterion of force of 0.01 eV/Å were used.

#### 3. Results

#### 3.1. Formation energy and binding energy of Mg<sub>47</sub>X structures

Formation energy and binding energy of  $Mg_{47}X$  structures were computed and shown in Table 1. The formation energy of a  $Mg_{47}X$ slab is the energy required to substitute a Mg atom with an X atom in a perfect  $Mg_{48}$  slab, which can be determined based on the equation below:

$$E_{f}(Mg_{47}X) = E_{slab}(Mg_{47}X) - E_{slab}(Mg_{48})$$
$$+E_{bulk}(Mg) - E_{bulk}(X)$$
(4)

where  $E_{\text{slab}}$  represents the total energy of a perfect slab without any stacking faults,  $E_{\text{bulk}}$  represents the atomic energy of the metallic element in its stable bulk structure, which were acquired from

**Fig. 2.** GSFE curve along the faulting pathway (a) from  $I_1$  to  $I_1'$  faulted slabs and (b) from perfect to  $I_2$  faulted slabs. The maximum  $\gamma$  value along  $I_1$  to  $I_1'$  and perfect to  $I_2$  pathways are denoted as  $\gamma_{us_1}$  and  $\gamma_{us_2}$ .

Materials Project [16]. The formation energy ( $E_f$ ) of Mg<sub>47</sub>X slab is in the unit of eV.

We have also determined the binding energy of a  $Mg_{47}X$  slab, which is the energy required to assemble the whole slab with isolated Mg and X atoms, as shown in the following equation:

$$E_{b} (Mg_{47}X) = E_{slab} (Mg_{47}X) - E_{slab} (Mg_{48})$$
$$+E_{isolated} (Mg) - E_{isolated} (X)$$
(5)

where  $E_{isolated}$  represents the energy of an isolated metal atom in vacuum. The binding energy ( $E_{b}$ ) is shown with respect to that of pure Mg slab and in the unit of eV.

As seen from Table 1, formation energy of Mg-X structures varied from -1.71 eV (Mg-Pt) to 2.04 eV (Mg-W), and binding energies of Mg-X structures varied from -6.71 eV (Mg-Ir) to 2.27 eV (Mg-K). From Table 1, an increasing tendency of binding energy ( $E_b$ ) with respect to the atomic radius (R) of alloying elements could be acquired, while for the formation energy there was no such relationships. To understand their contributions to the variation of GSFEs in Mg-X systems, statistical analysis and discussions were carried out and shown later in Section 4.2.

### 3.2. Generalized stacking fault energy curves for $I_1$ and $I_2$ faults in pure Mg

The fully optimized GSFE curve ( $\gamma$ -curve) along the faulting pathway from a perfect slab to an I<sub>2</sub> faulted slab, as well as that from an I<sub>1</sub> faulted slab to an I<sub>1</sub>' faulted slab, are plotted in Fig. 2. Along the minimum energy path,  $\gamma_{I_1}$ ,  $\gamma_{I_1}$  and  $\gamma_{I_2}$  represent the intrinsic stacking-fault energy of I<sub>1</sub>, I<sub>1</sub>' and I<sub>2</sub> faults, respectively, while  $\gamma_{us_1}$  and  $\gamma_{us_2}$  are the unstable stacking-fault energy along these two faulting pathways. In Fig. 1, since I<sub>1</sub> and I<sub>1</sub>' faulted slabs were two simulation structures with the center position of local I<sub>1</sub> faults on

adjacent atomic layers, the values of  $\gamma_{l_1}$  should be almost the same as that of  $\gamma_{l_1}$ .

Fig. 2 indicates that unstable SFEs give energy barrier of I<sub>1</sub> and I<sub>2</sub> faults, which were the maximum GSFE values on  $\gamma$ -curves along MEPs, near the middle point of the transition process where the Burgers vector  $\mathbf{\tilde{b}} = \frac{1}{6} \begin{bmatrix} 10\bar{1}0 \end{bmatrix}$ . As the energy barrier describes the energy required for the transition process between two endpoints of a reaction, in this case,  $\gamma_{us_1}$  gives the required energy for a Mg slab to transform from an I<sub>1</sub> faulted structure to an I<sub>1</sub>' faulted structure, and similarly,  $\gamma_{us_2}$  gives the required energy for a Mg slab to transform from a perfect structure to an I<sub>2</sub> faulted structure. The intrinsic SFEs at the endpoints of the  $\gamma$ -curves correspond to the stable stacking-fault energy of I<sub>1</sub> (or I<sub>1</sub>') faulted and I<sub>2</sub> faulted structures.

The intrinsic and unstable stacking-fault energies of  $I_1$  and  $I_2$  in pure Mg structure are summarized in Table 2, together with some data in literature for comparison. From the GSFE data from this work and literature in Table 2, we note that the values of  $\gamma_{l_2}$  are usually about twice that of  $\gamma_{l_1}$ , and values of  $\gamma_{us_1}$  were only slightly smaller than that of  $\gamma_{us_2}$ . CINEB-calculations for  $\gamma$ -curves of  $I_1$  and  $I_2$  in alloying systems were also performed, and values for GSFEs are shown in Table 1, from which similar relationships between  $\gamma_{l_1}$ and  $\gamma_{l_2}$  were observed.

### 3.3. Intrinsic and unstable stacking-fault energies of $I_1$ and $I_2$ in $Mg_{47}X$ structures

As alloying elements were added into Mg slab, there was a variation in basal-plane GSFEs of Mg-X system due to the alloying effects. Calculated  $\gamma_{l_1}(\gamma_{l_1})$ ,  $\gamma_{us_1}$ ,  $\gamma_{l_2}$  and  $\gamma_{us_2}$  values in Mg-X systems given in Table 1 were plotted in Fig. 3 with respect to atomic radius of alloying elements X. A negative relationship between

Q. Dong et al. / Journal of Materials Science & Technology xxx (2018) xxx-xxx

**Fig. 3.** Variation of calculated GSFEs including (a) intrinsic SFE of I<sub>2</sub>, (b) intrinsic SFE of I<sub>1</sub>, (c) unstable SFE of I<sub>2</sub> and (d) unstable SFE of I<sub>1</sub>, with respect to atomic radius of alloying elements. The doping concentration is 25 at.% in doping plane and 2.08 at.% in Mg-X system.

|                 |                 |                                 |   |                                 |                                 |                                 |                                 |                                 |   |                                  |                                  |                                  |                                  |                                  |                                  |  |

Fig. 4. Periodic table with valence electron configuration and unstable SFEs of I<sub>2</sub> of Mg-X alloying systems.

GSFEs and atomic radius of alloying elements could be observed in Fig. 3, and the range of variations of GSFEs in Mg-X systems could also be acquired through Table 1 and Fig. 3. Comparing to intrinsic SFEs, the variations of unstable SFEs of I<sub>1</sub> as well as I<sub>2</sub> were more strongly influenced by the alloying elements, and variations of intrinsic SFE of I<sub>2</sub> were more strongly influenced than instrinsic SFEs of I<sub>1</sub>. For unstable SFEs of I<sub>1</sub> and I<sub>2</sub> faults, the variation tendency and strength of the dependence on alloying elements were similar. Intrinsic SFEs of I<sub>1</sub> varied from  $-8.2 \text{ mJ/m}^2$  (Mg-Ta) to  $26.9 \text{ mJ/m}^2$ (Mg-Ir), while unstable SFEs of I<sub>1</sub> varied from  $22.9 \text{ mJ/m}^2$  (Mg-K) to  $154.9 \text{ mJ/m}^2$  (Mg-Re). In the case of I<sub>2</sub> faults, intrinsic SFEs varied from  $-2.6 \text{ mJ/m}^2$  (Mg-Bi) to  $72.6 \text{ mJ/m}^2$  (Mg-Ru) and unstable SFEs varied from 28.1 mJ/m<sup>2</sup> (Mg-K) to 156.7 mJ/m<sup>2</sup> (Mg-Re). Among 43 alloying elements, Al, Bi, Ga, Hg, In, K, La, Pb, Sm, Sn, Tl and Y reduced GSFEs in Mg-X alloys, while Ag, Co, Cr, Ir, Li, Ni, Pd, Pt, Rh, Ru, Tc and V increased GSFEs. A detailed discussion on how alloying elements affect SFEs will be provided in Section 4.2.

#### 4. Discussion

### 4.1. Relationships between $\gamma_{I_1}$ and $\gamma_{I_2}$ in Mg-X systems

To find out the relationships between  $\gamma_{l_1}$  and  $\gamma_{l_2}$ , further statistical analysis was performed. Pearson Correlation Coefficient was

#### Q. Dong et al. / Journal of Materials Science & Technology xxx (2018) xxx-xxx

chosen for evaluating the linear relationship between variables X and Y:

$$r(X,Y) = \frac{\operatorname{cov}(X,Y)}{\sigma_X \sigma_Y} \tag{6}$$

where cov(X, Y) represents the covariance between X and Y, and  $\sigma_X$ ,  $\sigma_Y$  represents the standard deviations for X and Y, respectively. Pearson Correlation Coefficient r is a number in the range of [-1, 1] to measure strength and direction of the linear relationship between two variables, and a larger absolute value of r indicates a stronger relationship between the variables.

Calculations performed through Eq. (6) gives the correlation coefficient  $r(\gamma_{l_1}, \gamma_{l_2}) = 0.73$ . It should be noted that the correlation coefficient value of 0.73 indicates a strong positive relationship between SFEs of  $I_1$  and  $I_2$ . We also calculated the correlation coefficients  $r(\gamma_{l_2}, \gamma_{us_2}) = 0.76$ , and  $r(\gamma_{us_1}, \gamma_{us_2}) = 0.97$ .

As shown in Fig. 1, the atomic configuration at the stacking-fault interface of I<sub>1</sub> and I<sub>2</sub> faults forms local FCC-like layer structure (ABC) inside HCP layer structure (AB). The local FCC stacking introduces a characteristic stacking-fault energy, which arises from changes in the second-neighbour sequences of the planes. Although the atomic-configuration changes from HCP to local FCC exist in both  $I_1$  and  $I_2$  faults, there are only one such change in  $I_1$  but two in  $I_2$ , leading to an approximated relationship of  $\gamma_{I_1} = \frac{1}{2}\gamma_{I_2}$  [27]. The values of  $\gamma_{l_1}/\gamma_{l_2}$  rate for Mg-X systems are calculated, and the average value of  $\gamma_{I_1}/\gamma_{I_2}$  equals to 0.53, in agreement with the approximated relationship of 0.5.

#### 4.2. Contributing factors to $\gamma_{us_2}$ in Mg<sub>47</sub>X structure

To figure out possible factors that may contribute to the variations of GSFEs in Mg-X alloying systems, we have obtained the atomic radius (*R*), 1st and 2nd ionization energy  $(E_{i_1} \text{ and } E_{i_2})$  [17], number of valence electrons  $(N_{ve})$ , and the equilibrium volume  $(V_{hcp})$  and bulk modulus  $(\kappa_{hcp})$  for HCP structures of alloying elements [18], formation energy for Mg-X alloying systems  $(E_f)$  and binding energy for Mg-X alloying systems  $(E_{\rm b})$ , as shown in Table 1. A periodic table with unstable SFEs of I<sub>2</sub> was also provided to exhibit the relation between the valence electron configuration and GSFEs in Mg-X alloying systems, as shown in Fig. 4. According to Table 1 and Fig. 4, one can see that alloying elements with more valence electrons would increase the GSFEs in Mg-X alloys.

For further statistical analysis to figure out the contributing factors to the variations of basal-plane GSFEs in Mg-X systems, unstable SFE of I<sub>2</sub> ( $\gamma_{us_2}$ ) is selected as a representative for the intrinsic and unstable SFEs of I1 and I2, since strong positive linear relationships among these 4 basal-plane GSFE variables in Mg-X systems were achieved in Section 4.1. Multiple correlation matrix Table 3

Correlation matrix between  $\gamma_{us_2}$  and properties of alloying element X and Mg-X systems.

between  $\gamma_{us_2}$  and the selected properties of alloying elements as well as Mg-X alloying systems was computed, as shown in Table 3.

Seen from Table 3, the ranking of most possible properties that contribute to basal-plane GSFEs is  $\kappa_{hcp}$ ,  $V_{hcp}$ ,  $E_b$ , R,  $E_{i_1}$  and then  $E_f$ . The positive values of correlation coefficients between  $\kappa_{hcp}$  and  $E_{i_1}$ and  $\gamma_{us_2}$  in Mg-X binary alloying systems indicate that the addiction of alloying elements with lower bulk modulus or lower 1 st ionization energy would decrease GSFEs in Mg-X alloy. In contrast, negative correlation coefficients indicate that alloying elements with larger equilibrium volume, higher binding energy or larger atomic radius would decrease GSFEs. The absolute value of correlation coefficient between  $E_f$  and  $\gamma_{us_2}$  is too small to convince a certain relationship between formation energy of alloying elements and GSFEs. It should be noted that R and  $V_{hcp}$  both describe the size feature of alloying elements, and the correlation coefficient between R and  $V_{hcp}^{1/3}$  is 0.87, which indicates a strong positive linear relationship between these two factors, thus in further analysis atomic radius of alloying elements has be left out to avoid double-counting.

To get a visual representation of relationships between  $\gamma_{us_2}$  and the most contributing factors  $\kappa_{hcp}$ ,  $V_{hcp}$  and  $E_b$ , several scatter charts were plotted with the vertical axis of  $\gamma_{us_2}$  and the horizontal axis of  $\kappa_{hcp}$ ,  $V_{hcp}$ , and  $E_b$  respectively, as shown in Fig. 5, in which we could see how these three factors influence the basal-plane GSFEs in Mg-X binary systems. It could be concluded that alloying elements with lower bulk modulus would be favorable as solute addition to reduce GSFEs in Mg alloys. We also noted that alloying elements with larger equilibrium volumes would be better choices to reduce GSFEs in Mg alloys. GSFEs also varied with the binding energy  $E_{\rm b}$ , and Mg-X structures with higher binding energies tended to have a lower GSFE. In summary, addition of alloying elements with lower  $\kappa_{hcp}$ , larger  $V_{hcp}$ , and higher  $E_b$  to Mg<sub>47</sub>X slabs would exhibit lower GSFEs, which means the binary alloying system would yield a better ductility.

Two alloying elements, Ni and K, are selected to explain the alloying effects of these dominating factors mentioned above. From Table 1, taking unstable SFE of  $I_2$  as an

Fig. 5. Variation of calculated unstable SFE of I2 with respect to (a) bulk modulus of alloying elements, (b) binding energy of Mg47X structures and (c) HCP volumes of alloying elements.  $\gamma_{us_2}$  values are marked with vertical axis, and  $\kappa_{hcp}$ ,  $V_{hcp}$  and  $E_b$  values are marked with horizontal axis.

**Fig. 6.** Charge density iso-surface figures of perfect slabs for (b) pure Mg and Mg alloyed with Ni (a) and K (c). The yellow color indicates a high electron density and the blue color indicates a low electron density. The doping concentration is 25 at.% in doping plane and 2.08 at.% in Mg-X system.

example,  $\gamma_{us_2}$  (Mg<sub>48</sub>) = 89.6mJ/m<sup>2</sup>,  $\gamma_{l_2}$  (Mg<sub>47</sub>Ni) = 106.8mJ/m<sup>2</sup>,  $\gamma_{l_2}$  (Mg<sub>47</sub>K) = 28.1mJ/m<sup>2</sup>, which means Ni-alloying increases the basal-plane GSFEs and K-alloying decreases GSFEs remarkably. Seen from Table 1, element Ni with small *R*, small  $V_{hcp}$ , high  $\kappa_{hcp}$  and low  $E_b$ , compared to those of Mg, raises the basal-plane GSFE values, while alloying element K with large *R*, large  $V_{hcp}$ , low  $\kappa_{hcp}$  and high  $E_b$  lowers GSFEs in the magnesium binary alloying systems, which also gives a convincing proof for the relationships we concluded above.

The charge density iso-surfaces of Mg-Ni, Mg-K and pure Mg are shown in Fig. 6. It is illustrated that in the Ni alloyed Mg slab, the charge density near doping plane is increased, which indicates that electrons are attracted to alloying atom Ni. This would lead to a higher GSFE value since there are more electron redistributions within the stacking-fault plane during the formation of an I<sub>1</sub> or I<sub>2</sub> fault. In addition, distance between adjacent atomic layers near Ni doped plane is decreased, which makes it difficult for the formation of local FCC structures in I<sub>1</sub> and I<sub>2</sub> faulted slabs, where a larger atomic layer separation is needed. In fully-relaxed pure Mg slab structures, the distance between the 6th and 8th atomic layers (Fig. 1) is 5.187Å for a perfect slab, 5.215Å for an  $I_2$  faulted slab, and 5.216Å for an I<sub>1</sub> faulted slab, which indicates that local FCC structures are formed around stacking-fault planes with a slightly bigger layer distance than perfect HCP structure, thus the formation of local FCC structure is favored with an expanded atomic layer separation. In contrast to Ni-alloying, K-alloying expels surrounding electrons and increases the layer distance around the doping plane, and thus decreases GSFEs. Thus, from this aspect, we can also note that alloying element with smaller atomic size and stronger binding energy to Mg usually will display larger GSFEs.

**Fig. 7.** Regression prediction for  $\gamma_{us_2}$  in Mg-*X* systems. The red dotted line is the trend line for prediction values, y = 0.99x, and a perfect prediction should be y = x. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

#### 4.3. Multiple regression analysis for $\gamma_{us_2}$ predictions

According to Section 4.2, the most contributing properties for multiple regression analysis are  $\kappa_{hcp}$ ,  $V_{hcp}$ ,  $E_b$  and  $E_i$ , which have strong linear relationsihps with  $\gamma_{us_2}$ . A multiple regression equation was established to predict the unstable stacking-fault energies of I<sub>2</sub> in Mg-X systems:

$$\gamma_{\rm us_2} = c_1 + c_2 \kappa_{hcp} + c_3 V_{hcp} + c_4 E_b + c_5 E_{i_1} \tag{7}$$

where  $c_1$ ,  $c_2$ ,  $c_3$ ,  $c_4$  and  $c_5$  are the linear coefficients for multiple regression. These coefficients were acquired through calculations,  $c_1 = 98.21$ ,  $c_2 = 0.16$ ,  $c_3 = -0.88$ ,  $c_4 = -1.84$ ,  $c_5 = -0.01$ . Since variables in different terms of Eq. (7) are not in the same unit, where  $\kappa_{hcp}$  is in GPa,  $V_{hcp}$  is in Å<sup>3</sup>,  $E_b$  is in eV and  $E_{i_1}$  is in kJ/mol, the coefficients of each term are not standardized, and they could only give numerical expressions of the approximation equation instead of how these factors contribute to  $\gamma_{us_2}$ . With the solved values of linear coefficients, Eq. (7) was used to predict the values for  $\gamma_{us_2}$  with  $\kappa_{hcp}$ ,  $V_{hcp}$ ,  $E_b$  and  $E_{i_1}$  of Mg-X systems. To visualize the goodness of fit of this prediction equation, predicted  $\gamma_{us_2}$  values with respect to DFT-calculated  $\gamma_{us_2}$  values was plotted in Fig. 7. The goodness of fit of prediction values to DFT-calculated values could be explained using the multiple correlation coefficient between the predicted values and DFT-calculated values for  $\gamma_{us_2}$ , which could be noted as  $r(pre.\gamma_{us_2}, cal.\gamma_{us_2}) = 0.92$ , and the square of correlation coefficient  $r^2 = 0.84$ . The high coefficient value indicates a strong equality relationship between the equation-predicted and DFT-calculated  $\gamma_{us_2}$  values, and the high  $r^2$  value also indicates that 84% of  $\gamma_{us_2}$  values could be explained using the prediction with  $\kappa_{hcp}$ ,  $V_{hcp}$ ,  $E_b$  and  $E_{i_1}$ 

As mentioned before, Mg alloys with lower basal-plane GSFEs could activate non-basal slips and therefore show better ductility. Also through the correlation matrix analysis, we have figured out the ranking of most contributing properties of alloying elements that affect GSFEs in Mg-X systems, and the ranking should be in the order of  $\kappa_{hcp}$ ,  $V_{hcp}$  and  $E_{\rm b}$ . Thus this ranking would help give some guidance for new alloys design, i.e. in order to achieve better ductility, alloying elements with lower bulk modulus, larger equilibrium

8

## **ARTICLE IN PRESS**

#### Q. Dong et al. / Journal of Materials Science & Technology xxx (2018) xxx-xxx

volume and higher binding energy in Mg alloys would be favored as the solute addition. Moreover, bulk modulus takes the most important role among all the properties of alloying elements, and should be taken into first consideration during materials design. Furthermore, the multiple regression analysis offered a quantitative prediction for the basal-plane GSFE values in Mg-X systems, which could help predict ductility properties of new Mg alloys by calculating GSFEs with the known properties of alloying elements.

#### 5. Conclusions

In summary, according to DFT-calculated GSFEs of basal-plane stacking faults in binary Mg alloys, addition of alloying elements with various properties including bulk modulus, atomic radius, ionization energy and binding energy led to a large variation of GSFEs. Alloying elements including Al, Bi, Ga, Hg, In, K, La, Pb, Sm, Sn, Tl and Y among 43 metallic elements reduced the basal-plane GSFEs in Mg alloys, whilst Ag, Co, Cr, Ir, Li, Ni, Pd, Pt, Rh, Ru, Tc and V increased the GSFEs. Linear relationships between intrinsic and unstable SFEs for basal planes as well as the numerical relationship of  $\gamma_{l_1} = \frac{1}{2} \gamma_{l_2}$ were confirmed. Among the properties of alloying elements and Mg-X structures, the variation of basal-plane GSFEs were found strongly related to  $\kappa_{hcp}$ ,  $V_{hcp}$ ,  $E_b$ , R,  $E_{i_1}$  and  $E_f$ . The alloying elements with lower bulk modulus, larger equilibrium volume, higher binding energy, larger atomic radius, lower 1 st ionization energy would reduce the GSFEs in Mg-X alloys. A prediction model for basal-plane GSFEs in Mg alloys was also built to give quantitative predictions for GSFEs in new Mg alloys, which offer guidance for new Mg alloys design with better ductility.
